Phyllotaxy
entire-2

A B S T R A C T

The spatiotemporal localization of the plant hormone auxin acts as a positional cue during early leaf and flower organogenesis. One of the main contributors to auxin localization is the auxin efflux carrier PIN-FORMED1 (PIN1). Phylogenetic analysis has revealed that PIN1 genes are split into two sister clades; PIN1 and the relatively uncharacterized Sister-Of-PIN1 (SoPIN1). In this paper we identify entire-2 as a loss-of-function SlSoPIN1a (Solyc10g078370) mutant in Solanum lycopersicum. The entire-2 plants are unable to specify proper leaf initiation leading to a frequent switch from the wild type spiral phyllotactic pattern to distichous and decussate patterns. Leaves in entire-2 are large and less complex and the leaflets display spatial deformities in lamina expansion, vascular development, and margin specification. During sympodial growth in entire-2 the specification of organ position and identity is greatly affected resulting in variable branching patterns on the main sympodial and inflorescence axes. To understand how SlSoPIN1a functions in establishing proper auxin maxima we used the auxin signaling reporter DR5: Venus to visualize differences in auxin localization between entire-2 and wild type. DR5: Venus visualization shows a widening of auxin localization which spreads to subepidermal tissue layers during early leaf and flower organogenesis, showing that SoPIN1 functions to focus auxin signaling to the epidermal layer. The striking spatial deformities observed in entire-2 help provide a mechanistic framework for explaining the function of the SlPIN1 clade in S. lycopersicum.

1. Introduction

In plants, cell fate and subsequent tissue formation are mainly determined by positional information rather than cell lineage. The plant hormone auxin acts as a positional cue for proper patterning in many developmental processes, including embryogenesis (Friml et al., 2003; Cheng et al., 2007), leaf and leaflet initiation (Cheng et al., 2007; Reinhardt et al., 2000, 2003a, 2006; Koenig et al., 2009), vascular patterning (Cheng et al., 2006; Mattsson et al., 1999; Mattsson et al., 2003; Scarpella et al., 2006), root organogenesis (Overvoorde et al., 2010) and flower initiation (Reinhardt et al., 2000; Benková et al., 2003; Heisler et al., 2005). Auxin presence guides the organization of these processes by inducing changes in transcriptional responses and by affecting cell wall physical properties. The multifaceted role of auxin necessitates a coordinated regulation of auxin influx and efflux carriers that guide auxin transport in a polar fashion that together make up the Polar Auxin Transport (PAT) network.

PAT facilitates auxin action to be precisely coordinated in both a localized and concentration dependent manner. Unlike other known plant hormones, auxin is actively transported in a directional fashion, allowing the creation of spatio-temporally regulated auxin concentrations. The largest contributors of directional transport in the PAT system are the PIN-FORMED (PIN) auxin transporters (Gälweiler et al., 1998; Müller et al., 1998; Friml, 2003; Paponov et al., 2005). Most PINs (PIN1, PIN2, PIN3, PIN4 and PIN7) accomplish directional transport by localizing asymmetrically on the plasma membrane of a cell (Vieten et al., 2007), transporting auxin out of the cell in the direction of PIN localization. Auxin, as a weak acid, is freely taken up into a cell; therefore transport of auxin out of the cell by PIN proteins is the determining factor for directional auxin movement (Vieten et al., 2007; Leyser, 2005; Friml, 2010). The cumulative effect of PIN localization at the tissue level is spatial variation in auxin concentration across the developing organ and the generation of small regions of high auxin concentration called auxin maxima (Okada et al., 1991; Guenot et al., 2012; Scarpella et al., 2010)

The understanding of PIN-FORMED (PIN1) contribution to plant patterning began with the characterization of the Arabidopsis
A handful of studies that characterize PIN gene function outside the model species *Arabidopsis thaliana* and only one functional study, in *Medicago truncatula*, describing the sop1 mutant smooth leaf margin 1 (*slm1*) (Zhou et al., 2011a). Conservation of PIN-regulated developmental modules is likely species-specific and the extent of divergence in these modules needs to be addressed by analysis of PIN gene function in other species.

*Solanum lycopersicum* is a model system for studying shoot organogenesis, owing to the large and easily accessible apical meristem and sympodial mode of shoot growth after floral transition. *S. lycopersicum* has also been used specifically to understand auxin directed developmental mechanisms such as *SisopIN1a* protein localization in developing organs (Koenig et al., 2009; Bayer et al., 2009; Shani et al., 2010) and effects of auxin application on organogenesis (Reinhardt et al., 2000, 2003a; Koenig et al., 2009; Naz et al., 2013). Although *S. lycopersicum* is used extensively as a model system for understanding auxin directed development there is little functional work on PIN genes within this species. RNAi knock-down experiments are difficult owing to sequence similarity of the target sequences and have yielded limited insight into *PIN1* function in *S. lycopersicum* (Pattison and Catalá, 2012). There are 10 *PIN* genes in *S. lycopersicum*, three of which reside in a highly supported phylogenetic clade with *AtPIN1* (Bennett et al., 2014; O’Connor et al., 2014; Pattison and Catalá, 2012; Nishio et al., 2010).

To determine *PIN1* function in a broader evolutionary context, we analyzed the function of *SoPIN1* outside the limited context of the Brassicaceae member *A. thaliana*. This study identifies *entire*-2, a previously uncharacterized *SisopIN1a* loss of function mutant in *S. lycopersicum*. Phenotypic characterization revealed the role of *SisopIN1a* in spatial organization during organogenesis and in leaf, flower, and fruit development. Auxin maxima and auxin-induced gene activity were visualized using an auxin inducible promoter-reporter system, DR5: Venus, and showed that *SisopIN1a* loss of function causes a broadening of auxin localization in the apical, inflorescence, and floral meristems and at sites of formation of vasculature causing aberrant developmental responses. We conclude that *SisopIN1a* regulates auxin patterning by allowing auxin movement in tissue specific cell layers to create a correct spatio-temporal pattern of auxin concentrations needed to guide organ initiation and subsequent morphogenetic processes.

**2. Results**

**2.1. There was a SoPIN1 gene duplication event prior to the diversification of the Solanaceae**

In *S. lycopersicum*, there is one true *AtPIN1* ortholog, *SIPIN1* (*Solyc03g118740*), and two *SoPIN1* genes, *SisopIN1a* (*Solyc10g078370*) and *SisopIN1b* (*Solyc10g080880*) (Fig. 1) (Pattison and Catalá, 2012; Nishio et al., 2010). Previous phylogenetic analysis places both *SisopIN1a* and *SisopIN1b* genes together on a single branch tip, suggesting a recent *SoPIN1* gene duplication event in the branch leading to *S. lycopersicum* (Bennett et al., 2014; O’Connor et al., 2014). These reports suggested that a duplication event in the *SoPIN1* clade in *S. lycopersicum* occurred roughly sometime after the divergence between *S. lycopersicum* and *Mimus guttatus* (Bennett et al., 2014; O’Connor et al., 2014). To gain a more precise understanding of the history of the *SoPIN1* clade, we performed phylogenetic analysis on *PIN1* and *SoPIN1* genes sampling Solanaceae more extensively by including *Capsicum annuum*, *Nicotiana benthamiana*, *Solanum habrochaites*, *Solanum lycopersicum*, *Solanum pennelli*, *Solanum pimpinellifolium*, and *Solanum tuberosum*. In addition, we included seven other representative Eudicot species (*Arabidopsis thaliana*, *Citrus...
clementina, Capsella rubella, Cucumis sativus, Medicago truncatula, Mimulus guttatus, and Solanum pimpinellifolium, S. clementina, Capsella rubella, Cucumis sativus, Medicago truncatula, and Mimulus guttatus (Fig. 1A), and used A. thaliana PIN3 as an outgroup. We performed phylogenetic analysis using the RAxML maximum likelihood method (Stamatakis, 2006) with orthologous cDNA sequences of SoPIN1 and SIPIN1 genes. Bootstrap analysis was performed on 1000 runs to obtain statistical confidence.

PIN1 genes fall into two highly supported sister clades, as shown in previous work (Bennett et al., 2014; O’Connor et al., 2014), one group which we will continue to refer to as PIN1, where AtPIN1 (AT1G73590) resides, and a second clade, Sister-of-PIN1 (SoPIN1) (Fig. 1B). All species sampled have at least one gene represented in each of the PIN1 and SoPIN1 clades, with the exception of A. thaliana and the closely related species C. rubella (Fig. 1A and B), demonstrating a likely loss of the SoPIN1 clade in Brassicaceae, as recently reported (Bennett et al., 2014; O’Connor et al., 2014). Within the SoPIN1 clade, Solanaceae SoPIN1 genes are split into two clear groups - each with at least one member from each Solanaceae species sampled (Fig. 1B). All other Eudicot species have genes that fall outside these two Solanaceae specific groups, suggesting the SoPIN1 duplication event occurred just prior to Solanaceae speciation. The function of these duplicated SoPIN1 genes has never been explored explicitly.

2.2. e-2 has a stop codon in SsSoPIN1a

To compare the function of SoPIN1 and PIN1 genes in Solanaceae to the function of PIN1 in A. thaliana, we screened the Tomato Genetics Research Center (TGRC) mutant database for candidate pin1 and sopin1 mutants in S. lycopersicum. Guided by the phenotypic characterization of A. thaliana and M. truncatula pin1 mutants, we searched for monogenic mutant lines located in the approximate genomic regions of the S. lycopersicum SIPIN1, SsSoPIN1a and SsSoPIN1b genes that displayed leaf phenotypes. In close proximity to SIPIN1 on Chromosome 3, there are two mutant lines that exhibit aberrant leaf phenotypes: divaricata (div) and solanifolia (sf). Both of the SoPIN1 genes, SsSoPIN1a and SsSoPIN1b reside in close proximity to each other on Chromosome 10, along with three leaf phenotype mutants: oivacea (oi), entire-2 (e-2), and restricta (res). We grew all five mutant lines and scored them for spatial arrangement phenotypes in shoot and leaf morphology similar to phenotypes of A. thaliana and M. truncatula sopin1 (slm) mutants (Gälweiler et al., 1998; Guenot et al., 2012; Zhou et al., 2011b). Of the mutant lines, sf, e-2, and div were characterized as having leaf phenotypes (S1 Figure), but only e-2 and sf possessed abnormalities similar to what was measured in the M. truncatula sopin1 mutant and atpin1 mutant lines, including aberrant vasculature, fused cotyledons, and laminar tissue (Gälweiler et al., 1998; Guenot et al., 2012; Zhou et al., 2011b). Next we compared the nucleotide sequences of all three PIN1 genes in sf, e-2, and div mutant lines and found that all sequences were identical to that in their wild type background with the exception of e-2. The SsSoPIN1a sequence in e-2 plants harbors a single nucleotide change from C to T at position 490 (C>T490) causing a premature stop codon in the translated amino acid sequence (Fig. 2A), suggesting e-2 as a candidate sopin1 loss of function mutant. Organ patterning varied considerably between e-2 individuals, and the most consistent phenotype was a deviation from the wild type spiral phyllotactic pattern. This aspect of the phenotype was
2.3. \( C^{-T490} \) co-segregates with the \( e^{-2} \) phenotype

We tested if \( C^{-T490} \) was responsible for the \( e^{-2} \) phenotype by asking if \( C^{-T490} \) co-segregates with the phyllotaxy phenotype. Since the \( e^{-2} \) phenotype varied considerably between individuals (described in detail later), we used presence/absence of spiral phyllotaxy to score phenotypes, as absence of spiral phyllotaxy was the most consistent phenotype found in \( e^{-2} \) plants. We crossed \( e^{-2} \) with the wild type background, self-pollinated the heterozygous progeny, and scored for presence and absence of the spiral phyllotactic pattern in the F2 population (\( n = 117 \)). Plants were phenotyped 30 days after germination, when Leaf 1 to ~ Leaf 7 are clearly visible. In the segregating F2 population, 81.8% individuals homozygous for the wild type allele possessed spiral phyllotaxy, while 93.7% of the heterozygotes exhibited the spiral phyllotactic pattern (Fig. 2B). Of the individuals homozygous for \( C^{-T490} \), 86.4% scored as having an absence of a spiral phyllotaxy (Fig. 2B). Assuming plants heterozygous and homozygous for the wild type allele display a spiral phyllotactic pattern, the segregation of the phyllotaxy phenotype did not differ from expected based on genotype (chi-squared test, \( p-value = 1.00 \)). These results indicate that the \( C^{-T490} \) SNP in \( e^{-2} \) is a likely candidate responsible for the deviation in spiral phyllotaxy seen in \( e^{-2} \) and further supports our hypothesis that \( e^{-2} \) is a \( slsopin1a \) mutant.

2.4. \( e^{-2} \) phenotype can be complemented with a functional PIN1 gene

To further establish that the \( e^{-2} \) phenotype is caused by a lack of \( slsopin1a \) function, we asked if a functional PIN1 protein could rescue the phyllotaxy phenotype in \( e^{-2} \). Guided by a previous study that used an \( AtPIN1 \) construct to rescue the \( slm1/mtsopin1 \) mutant phenotype (Zhou et al., 2011a), we tested if a functional copy of \( AtPIN1 \) is able to rescue \( SlSoPIN1a \) protein function. We evaluated the presence or absence of spiral phyllotaxy in a population (\( n = 117 \)) homozygous for \( C^{-T490} \) and segregating for \( pPIN1: PIN1: GFP \), a construct containing a functional \( PIN1 \) gene and promoter from \( A. thaliana \) (Bayer et al., 2009). All individuals of the population were genotyped as homozygous for \( C^{-T490} \) and \( 72.22\% \) of the population genotyped positive for the \( pPIN1: PIN1: GFP \) construct. If \( pPIN1: PIN1: GFP \) is capable of rescue, we would expect approximately \( 72.22\% \) of the population to have a spiral phyllotactic pattern. We found \( 77.16\% \) of the population displayed the expected rescued spiral phyllotactic phenotype, which is not significantly different from expected (chi-squared test, \( p-value = 0.3149 \)). Most individuals genotyped for \( pPIN1: PIN1: GFP \) (\( 88\% \)) displayed the wild type spiral phenotype (Fig. 2C). Further, leaves in complemented individuals showed a similar angle of divergence to that found in WT (S2 Figure A). Thus a functional \( PIN1 \) is capable of rescuing the aberrant phyllotaxy found in \( e^{-2} \) individuals homozygous for \( C^{-T490} \).

2.5. \( C^{-T490} \) causes loss of \( slsopin1a \) function in \( e^{-2} \)

We next asked how \( C^{-T490} \) affects gene function at the protein level. Differences at the translational level were assessed by the presence or absence of the \( slsopin1a \) protein using an antibody raised against the \( slsopin1a \) sequence (Bayer et al., 2009). In wild type, we observed \( SlSoPIN1a \) protein localization in incipient primordia and provascular tissue (Fig. 2D) as observed previously (Bayer et al., 2009). In contrast, \( SlSoPIN1a \) protein was always absent in \( e^{-2} \) apices (Fig. 2E and G). In all, we performed immunolocalization on twelve apices of both \( e^{-2} \) and wild type.
SlSoPIN1a protein localization was never observed in e-2 individuals, while SlSoPIN1a antibody presence was found in all but one WT apex sampled (Fig. 2H). These results indicate that C-T490 does not affect SlSoPIN1a transcription, but prevents accumulation of functional SlSoPIN1a by preventing translation in e-2 apices, further confirming that e-2 is a loss of function slsopin1a mutant.

2.6. SlSoPIN1a regulates phyllotaxy

We quantified how e-2 plants deviate from spiral phyllotactic patterning by measuring the leaf divergence angle in both wild type (n = 114) and e-2 (n = 124). S. lycopersicum spiral phyllotactic patterning generally follows a regular repeating angle of

Fig. 3. SlSoPIN1a regulates phyllotactic patterning in S. lycopersicum. (A) and (C) wild type plants displaying spiral phyllotactic patterning. (B) and (D) e-2 plants displaying a distichous phyllotaxy. (E) Divergence angles across leaves 1–8. (F) to (H) Photographs of apical meristems from (F) wild type and (G) e-2. Dotted lines represent how measurements were obtained for length and width in (F) and (G). (H) Differences in meristem size between wild type (gray) and e-2 (blue). *** indicates p-value < 0.0005. Scale bars = 0.2 mm in (F) and (G).
Fig. 4. Leaf development in e-2. (A) to (F) Leaf 2 from two week old plants cleared with chlorate showing midvein development (A) and (B), vascular tissue near leaf margin (C) and (D), and trachery branching (E) and (F) in wild type (A), (C), and (E) and e-2 (B), (D), (F). (G) and (H) Lamina tissue from Leaf 4 (G) wild type and (H) e-2 three week old plants. (I) and (J) Leaf 4 of five week old plants showing e-2 leaves are larger and less complex than wild type. (J) Bar graph illustrating average leaflet number of Leaf 4 leaves from six week old plants, showing e-2 (blue; n = 70) leaves are significantly less complex compared to wild type (gray; n = 49). Error bars represent Mean ± Standard Error (SE). (K) Representative binary terminal leaflet outlines from four week old plants. (L) Boxplot showing leaflet area from fully expanded leaves 1 and 2 of wild type (gray; n = 316) and e-2 (blue; n = 315). (M) Principal Components (PC) 1–4 illustrated as leaf outlines which include –1 standard deviations (purple) and +1 standard deviations (orange) along each axis and mean outline (gray). (N) Scatter plot of PC1 and PC3 obtained from elliptical fourier analysis performed on leaf outlines from wild type (black) and e-2 (blue). (O) Average terminal leaflet outline from Leaves 1–4, derived from elliptical fourier analysis. Welch's t-test P-value < 0.01 = **, P-value < 0.0001 = ***. Scale bars = 1 mm in (A) to (D), 0.1 mm in (E) to (H), and 2 cm in (I).
divergence, with leaves emerging around 137.5° (Kuhlemeier, 2007) (Fig. 3A-E). In wild type, we measured divergence angles clustered around 137.5° as expected, while in e-2, the divergence angles varied extensively, with measurements clustering in the upper limits of divergence ~ 180° (Fig. 3E). Around half of e-2 individuals (44.31%) display a dichotious or decussate phyllotaxy, as leaves alternatively emerge at around 180° and 90° (S2 Figure A). There are few known plant mutants that switch phyllotactic pattern and in three characterized phyllotaxy mutants meristem size has been attributed as a possible determining factor (Jackson and Hake, 1999; Prasad et al., 2011; Itoh et al., 2012). The spatial constraints of meristem size influence where new auxin maxima can form to initiate new leaves. In order to assess if meristem size in e-2 is a contributing factor to the e-2 phyllotaxy phenotype, we measured the width and height of wild type (n = 34) and e-2 (n = 46) meristems (Fig. 3F-H). Overall e-2 meristems are significantly larger in height (Welch Two Sample t-test, p-value = 8.729e-06) but have no significant difference in meristem width (Welch Two Sample t-test, p-value = 0.1767) (Fig. 3I), suggesting meristem size may be a contributing factor to the aberrant phyllotaxy observed in e-2.

2.7. SlSoPIN1a regulates spatial identity during leaf development

One of the most striking phenotypes of e-2 is the improper specification of leaf tissues. During leaf initiation, midvein formation begins as auxin is transported subepidermally through the center of the newly established leaf (Reinhardt et al., 2003a; Heisler et al., 2005). The midveins of e-2 leaves are thickened and often indistinguishable from secondary vascular tissue, giving the appearance of multiple mid veins (S3 Figure A). This trend of thickened vasculature is also displayed in higher order veins, attributed to irregular spacing, resulting in fused veins and increased tracheary elements (Fig. 4A-F). Vasculature in the petiole is also affected in e-2, as cross sections through the petiole reveal a lack of separation of vascular bundles seen in wild type (S3 Figure F-K). In wild type lamina, blade tissue is smooth and lies flat, while e-2 leaf tissue shows bulging of intervenue tissue that worsens as development proceeds (Fig. 4G and H; S3 Figure B-E).

The leaves of e-2 are significantly less complex due to a reduction of secondary and intercalary leaflets (Welch Two Sample t-test, p = 0.00198 and 4.033e-15, respectively) (Fig. 4I and J). Leaf margins in e-2 have irregular lobing and sharp serrations compared to wild type (Fig. 4K). In order to quantify leaf shape explicitly, shape differences were derived from characterization of the terminal leaflet of mutant and wild type. Overall, e-2 leaflets have a significantly larger area (Welch Two Sample t-test, p = 4.220 e-16) (Fig. 4L) and have higher circularity, a measure of leaflet serration and lobing (Welch Two Sample t-test, p = 2.391e-13), than wild type individuals (S1 Table). We used Elliptical Fourier analysis (Kuhl and Giardina, 1982; Bonhomme et al., 2014) to quantify differences in shape through measurement of leaflet outlines. Using Principal Component Analysis (PCA), we visualized patterns of variance that exist between the wild type leaflets and tissues, although placement of these features is highly irregular. Taken together these results suggest SlSoPIN1a functions in proper spatial organization during leaf initiation and morphogenetic processes.

2.8. SlSoPIN1a regulates spatial patterning and specification of organ identity during sympodial growth

Studies have shown that PIN1-directed auxin transport is necessary for floral initiation and development (Reinhardt et al., 2000; Benková et al., 2003; Heisler et al., 2005). The role of PIN1 in floral organ and inflorescence development is particularly difficult to characterize in A. thaliana, owing to the lack of inflorescence initiation in ap1 mutants (Okada et al., 1991), therefore we were particularly interested in characterizing SoPIN1 function in flower development using e-2. In S. lycopersicum, monopodial growth begins as leaves initiate from a single monopodial meristem (MM). After the initiation of around 7–12 leaves at the MM, plants begin sympodial growth (Park et al., 2011) (Fig. 5A). At the start of sympodial growth the MM produces 1. an inflorescence meristem (IM) and 2. a sympodial meristem (SYM) (Fig. 5B). Sympodial growth is delayed in e-2 likely from a slower rate of initiating leaves (Welch Two Sample t-test, p-value = 0.019) (S3 Figure P). In wild type plants, sympodial growth continues on the main axis of the plant, reiterating through distinct sets of sympodial modules. Each sympodial module consists of a single leaf and an inflorescence branch (Fig. 5A). The SYM continues growth on the main axis of the plant while the sympodial inflorescence meristem creates an inflorescence branching structure by further sympodial branching to produce determinate floral organs.

The specification of flower or leaf can occur during sympodial growth on both the main axis and in the inflorescence in some plants. Within Solanaceae, it is not uncommon to see bracts subtending flowers, as seen in S. pennellii, S. habrochaites, and N. benthamiana (personal observation). However, in S. lycopersicum the IM always produces only floral units (Park et al., 2014). Surprisingly, in e-2, the inflorescence branching pattern is variable creating many variations of the sympodial branching module, including specification of complex leaves, simple leaves, and aborted leaf-like structures in between flower units of the e-2 inflorescence (Fig. 5C-J and K-M; S4 D and I Figure). In e-2, both the number of floral units and flower branching structures deviate from the wild type pattern of around five floral units, which normally creates a zig zag branching pattern (Fig. 5C and K). We utilized tissue specific gene expression data from early stages of inflorescence (Lippman et al., 2008) to analyze gene expression differences in SIPIN1, SlSoPIN1a and SlSoPIN1b (S6 Figure). Gene expression of SIPIN1 remains constant across sympodial inflorescence establishment, but the SoPIN1 genes (SlSoPIN1a and SlSoPIN1b) have greater variability throughout the different stages and even vary compared to each other, suggesting a possible subfunctionalization during inflorescence establishment. These results, along with e-2 phenotypic characterization during sympodial growth, suggest SlSoPIN1a influences both the architecture of the inflorescence and also the specification of inflorescence organs, possibly by changing gene expression levels during sympodial growth.

Flower differentiation proceeds by the initiation of concentric whorls of lateral organs - the sepals, petals, stamens, and carpels (Smyth et al., 1990). Plants that are incapable of transporting auxin, either through genetic or chemical disruption, are either unable to form flowers (Okada et al., 1991) or display aberrant floral organ specification and positioning (Okada et al., 1991). In both heterozygous and to a greater extent, homozygous e-2 individuals, flowers range in deformities from appearing unaffected to extremely disordered, including fusion of flower organs both
within whorls (Fig. 5P) and between whorls (Fig. 5R), loss and gain of organs, and a general increase in organ size (Fig. 5O; S4 Figure A-C). Differences in size and shape are continued into fruit development, as e-2 fruit are often elongated with problems in seed set and placental development (S5 Figure). The fruit and flower phenotypes in e-2 shows that SlSoPIN1a function results in altered organ initiation and morphogenesis during sympodial and flower growth. (A) Schematic example of branching patterns showing inconsistent branching in wild type compared to e-2. (B) Schematic illustrating meristem maturation in wild type S. lycopersicum. During monopodial growth leaves initiate on the monopodial meristem (MM). Sympodial growth begins as the MM transitions to a sympodial meristem (SYM) and an inflorescence meristem (IM). The IM produces a determinate floral meristem (FM), which terminates as a single flower (F). Sympodial branching continues on the inflorescence as a new IM is initiated. (C) to (J) Schematic examples of inflorescence branching patterns. (K) Wild type inflorescence and (L) and (M) e-2 inflorescences. Flower size in wild type (N) is smaller and flowers consistently show five petals, while e-2 flowers (O) and (P) are often larger having inconsistent petal number due to within whorl tissue fusion events. (P) and (R) organ fusion events are also observed between wholes, as seen (R) e-2 as stamens (sta) are fused to style (sty). Wild type style (Q). Scale bars →(K),(L),(M) is 2 cm, (N), (O), (P) is 10 mm, and (Q) and (R) is 1 mm.

2.9. e-2 shows more diffuse and larger auxin foci during leaf initiation and early leaf development

To visualize potential disruptions in auxin localization in e-2, we used an auxin-inducible promoter-reporter system, DR5: Venus. Within whorls (Fig. 5P) and between whorls (Fig. 5R), loss and gain of organs, and a general increase in organ size (Fig. 5O; S4 Figure A-C). Differences in size and shape are continued into fruit development, as e-2 fruit are often elongated with problems in seed set and placental development (S5 Figure). The fruit and flower phenotypes in e-2 shows that SlSoPIN1a function results in altered organ initiation and morphogenesis during sympodial and flower growth. (A) Schematic example of branching patterns showing inconsistent branching in wild type compared to e-2. (B) Schematic illustrating meristem maturation in wild type S. lycopersicum. During monopodial growth leaves initiate on the monopodial meristem (MM). Sympodial growth begins as the MM transitions to a sympodial meristem (SYM) and an inflorescence meristem (IM). The IM produces a determinate floral meristem (FM), which terminates as a single flower (F). Sympodial branching continues on the inflorescence as a new IM is initiated. (C) to (J) Schematic examples of inflorescence branching patterns. (K) Wild type inflorescence and (L) and (M) e-2 inflorescences. Flower size in wild type (N) is smaller and flowers consistently show five petals, while e-2 flowers (O) and (P) are often larger having inconsistent petal number due to within whorl tissue fusion events. (P) and (R) organ fusion events are also observed between wholes, as seen (R) e-2 as stamens (sta) are fused to style (sty). Wild type style (Q). Scale bars →(K),(L),(M) is 2 cm, (N), (O), (P) is 10 mm, and (Q) and (R) is 1 mm.

3. Discussion

3.1. e-2 is a sopin1 mutant

In an attempt to identify PIN1 and SoPIN1 loss of function lines in S. lycopersicum we searched the TGRC mutant database for monogenic mutant lines previously mapped to the same chromosome of the three known PIN1/SoPIN1 genes in S. lycopersicum: SlSoPIN1a (Soly10g078370), SlSoPIN1b (Soly10g080880), and SlPIN1 (Soly03g118740). In the mutant line e-2 we identified a C-T1000 change, which causes a premature stop codon in the
translated amino acid sequence of SlSoPIN1a (Fig. 2A). Complementation (Fig. 2B), co-segregation (Fig. 2C) and protein presence (Fig. 2D-F) experiments verify that e-2 is a loss of function mutant of SlSoPIN1a, a member of the SoPIN1 clade (Bennett et al., 2014; O’Connor et al., 2014; Abraham Juárez et al., 2015) (Fig. 1), sister to one of the most prolifically studied plant development genes, PIN1. We used detailed phenotypic characterization of the e-2 mutant and visualization of the auxin inducible promoter DR5:Venus in this genetic background to understand how SlSoPIN1 functions in maintaining spatial patterning during early leaf and flower organogenesis in S. lycopersicum.
3.2. SLSopIN1a facilitates auxin localization in the L1 layer to establish phyllotaxy

Classically described by the Hofmeister rule, and based on the observation that leaves develop farthest from previous leaf initiation events, positioning of leaf primordia on the apical meristem was thought to be restricted by an inhibitory field around existing primordia (Hofmeister, 1868). It is now widely accepted that the interaction of PIN1 and auxin is the leading mechanism underlying the Hofmeister spacing rule (Reinhardt et al., 2003a; Okada et al., 1991; Guenot et al., 2012; Smith et al., 2006; Jonsson et al., 2006). PIN1 proteins direct auxin towards auxin maxima, draining auxin from surrounding cells and thus inhibiting the creation of new auxin maxima and foci of leaf initiation nearby. Loss of SLSopIN1 function in e-2/slsopin1 plants results in deviations from spiral phyllotactic patterning, including a consistent switch to distichous and decussate patterns (Fig. 6A-H). A switch from spiral to decussate phyllotaxy has been observed in several mutants including abphyll in maize (Jackson and Hake, 1999), plethora (plt) triple knockdown plt3plt5plt7 in A. thaliana (Prasad et al., 2011), and decussate in rice (Itoh et al., 2012). In addition, pharmacological application of auxin transport inhibitor N-1-naphthylphthalamic acid (NPA) causes a phyllotactic switch (Prasad et al., 2011). Visualization of the auxin response reporter DR5: Venus reveals e-2/slsopin1 apices have a dramatic expansion of the auxin response, including extension into L1, L2, and subepidermal layers throughout the entire dome of the apical meristem (Fig. 3D-G). For establishing phyllotaxy, the importance of auxin transport in the L1 tissue layer has been proven extensively as 1. Models can accurately predict phyllotaxy while only incorporating information from the L1 layer (Smith et al., 2006; Jonsson et al., 2006); 2. Laser ablation of the L1 layer results in auxin transport defects (Reinhardt et al., 2003b). 3. PIN1 expression in the L1 layer is sufficient to restore phyllotactic patterning in atpin1 (Kierzkowski et al., 2013). In addition knockout of PIN1 in L1 and L2 abolishes lateral organ development, while knockout of PIN1 in L1 only affects patterning (Kierzkowski et al., 2013).Inferring auxin response as indicative of auxin localization, we conclude that SLSopIN1a functions to restrict auxin distribution to the L1 layer, specifying convergences points that demarcate leaf initiation to establish phyllotactic patterning.

Convergence point formation occurs as PIN polarity guides auxin flow to the same region and coincides with drainage of auxin from surrounding cells subepidermally. The lack of SLSopIN1a function in e-2/slsopin1a individuals likely causes build-up of auxin that results in drainage at multiple locations leading to aberrant broad internal auxin presence, explaining the subdermal DR5: Venus observed throughout e-2/slsopin1a apices (Fig. 6D; Fig. 7). The increase in auxin presence in e-2/slsopin1a meristems may elicit auxin induced cell wall acidification, which activates expansin proteins (Hager, 2003) or pectin demethylesterification (Peaucelle et al., 2012) and contribute to an increase in meristem size. Meristem size may also contribute to changes in phyllotaxy observed in e-2/slsopin1a (Fig. 3 F-H) as suggested in previously characterized lines with phyllotactic patterning abnormalities (Jackson and Hake, 1999; Prasad et al., 2011; Itoh et al., 2012). The increase in meristem surface area could allow auxin maxima to form further away from previous initiation events, which is what we observe as divergence angles cluster around 180° (Fig. 3E). Overall, the phyllotactic patterning observed in e-2/slsopin1a is likely the result of SLSopIN1a mediated auxin transport being impaired in the L1 layer, limiting the ability to demarcate proper convergence points and the secondary result of changes in physical restraints caused from increase in meristem size.

3.3. SLSopIN1a functions in spatial organization during leaf morphogenesis

Subsequent leaf morphogenetic processes also rely on the repeated pattern of PIN1 convergence at the epidermal surface and internal auxin transport from convergence points, as seen during leaflet initiation and serration and lobe development (Koenig et al., 2009; Scarpella et al., 2006; Hay and Tsiantis, 2006). In e-2 individuals, leaflet initiation is compromised as complexity is overall decreased (Fig. 4J) DR5: Venus localization patterns during leaflet formation indicate a widening of auxin flux inwards as auxin canalization occurs (Fig. 6I-N). This widening of auxin signaling and lack of refinement of internal auxin paths found in early developing e-2/slsopin1a leaf primordia likely contributes to the widened and fused vasculature observed in mature e-2/slsopin1a leaves (Fig. 4A-F; Fig. 7). Distortions in vascular development would also influence the spatial organization problems observed during later leaf development in e-2/slsopin1a mutants (Fig. 4G-O). The cumulative result of the many early problems in auxin directed leaf development in e-2/slsopin1a plants could be seen in the final leaflet shape, which is extremely varied (Fig. 4K). The importance of SLSopIN1a in both leaflet formation and leaf initiation is clear and the gene appears to function in directing auxin to specify proper placement of leaf developmental features. Since most leaf developmental processes are reiterative and self-directing, the aggregate effect of misplaced auxin at leaf initiation
shows cumulative results in the extremely aberrant final leaf phenotype seen in entire-2/slsopin1a plants.

3.4. **SoPIN1a functions in meristem maturation and organ specification**

Of all the PINs, PIN1 appears to be the most important for reproductive development (Reinhardt et al., 2000; Gälweiler et al., 1998; Okada et al., 1991; Vernoux et al., 2000). In *S. lycopersicum*, *SoPIN1a* functions in both the positioning and specification of lateral organs during sympodial shoot meristem and inflorescence development. The sympodial unit on the main axis in wild type plants consists of one complex leaf and an inflorescence, while e-2/slsopin1a possesses dramatic variation in number of inflorescences and leaf number per sympodial unit (Fig. 5A). The inflorescence unit of e-2/slsopin1a bears both flowers and leaf organs (Fig. 5C-J), which is unusual, as all varieties of *S. lycopersicum* bear inflorescences with only flower units (Fig. 5C and K) (Park et al., 2014). Meristems are thought to establish reproductive identity through a defined maturation process, in which the likelihood to produce leaf organs, often defined as “vegetativeness,” decreases over time and ends with the determinate floral meristem identity (Prusinkiewicz et al., 2007). The inflorescence in e-2/slsopin1a may mature slower than wild type and possess a higher degree of vegetativeness. This slowing of maturation could result in a maturity state similar to sympodial growth on the main axis (Fig. 5A), which would explain the presence of leaf-like organs in e-2/slsopin1a (Fig. 5D-J, L, M; S4 Figure D-I). This hypothesis would explain the occasional presence of complex leaves, which closely resemble main axis leaves on the inflorescence axis (S3 Figure E).

An alternative interpretation of the e-2/slsopin1a inflorescence phenotype is that the leaf organs found on the inflorescence are bracts – leaf like organs that subtend flowers. Wild type *S. lycopersicum* plants do not contain visible bracts, but in the Solanaceae reproductive branching systems manifest in a variety of ways (Park et al., 2014). In many green-fruited wild relatives of *S. lycopersicum*, the first determinate organ in a floral branching system is a leaf-like bract (Uppman et al., 2008; Lifschitz and Eshed, 2006). It has even been suggested that all Solanaceae inflorescences have bracts, but their development may have been suppressed early (Castel et al., 2010), as seen in *A. thaliana* (Long and Barton, 2000; Hepworth et al., 2006; Kwiatkowska, 2006; Kwiatkowska, 2008) and potentially in *S. lycopersicum* (Reinhardt and Kuhlemeier, 2002). Modulation of auxin localization may be an evolutionary strategy for transformation of inflorescence types. The phenotype of leaf-like organs found on e-2/slsopin1a inflorescences could be a modulation in inflorescence branching identity, allowing the development of visible bract units as seen in closely related wild species. The most recent *SoPIN1* duplication event in *S. lycopersicum* occurred sometime before Solanaceae radiation (Fig. 1B). It would be interesting to test if modulation of *PIN1* and *SoPIN1* gene expression regulates inflorescence branching identity in diverse range of species in Solanaceae. Recent gene duplication events in the *PIN1* clade are common across angiosperms, as revealed through phylogenetic analyses clades (Fig. 1A and B) (Bennett et al., 2014; O’Connor et al., 2014). These recently evolved paralogs may represent an evolutionary mechanism to finely tune auxin directed development. Only more functional work in *PIN1* and *SoPIN1* within closely related species can reveal evolutionary functional divergence in the larger *PIN1* clade.

3.5. **Subfunctionalization and functional redundancy of *PIN1* and *SoPIN1* genes across species**

Our current understanding of *PIN1* directed auxin transport has largely ignored the contribution of *SoPIN1* genes because the most intensely studied species, *A. thaliana*, has lost the *SoPIN1* clade (Fig. 1B) (Bennett et al., 2014; O’Connor et al., 2014). Most angiosperm species have at least one representative in each of the *SoPIN1* and *PIN1* clades (Fig. 1B) (Bennett et al., 2014; O’Connor et al., 2014). This level of conservation throughout angiosperm species suggests both *SoPIN1* and *PIN1* genes have conserved function in plant development. Evidence that *AtPIN1* and *SlSoPIN1a* share function is that both *AtPIN1* and *SlSoPIN1a* proteins show very similar expression patterns, localizing predominantly in the L1 layer and subepidermally directing auxin during leaf initiation events (Fig. 2E) (Bayer et al., 2009). Further support of shared function is results from our complementation experiment in which *AtPIN1* is capable of rescue of the e-2 spiral phyllotaxy (Fig. 2C and E). Even though *AtPIN1* and *SlSoPIN1a* likely share similar roles, the loss of function phenotype in both species is very different, implying functional divergence. Loss of *AtPIN1* function in *A. thaliana* results in loss of lateral organ initiation after flowering, while in e-2/slsopin1a, subdermal auxin flux is delayed and e-2/slsopin1a initiates leaves at a slower rate than wild type (S3 Figure P) and proceeds with subsequent lateral organ initiation events throughout the lifespan of e-2/slsopin1a plants. A likely reason for the extreme phenotype of the *atpin1* mutant is that *AtPIN1* holds the function of both the *SoPIN1* and *PIN1* clades resulting from the recent loss from any *SoPIN1* representative in *Brassicaceae* (Fig. 1) (Bennett et al., 2014; O’Connor et al., 2014).

With recent research in organisms outside *A. thaliana* we have begun to uncover the possible evolutionary consequences of subfunctionalization of *PIN1* and *SoPIN1* genes. The *SoPIN1* and *PIN1* gene have distinct functions at the tissue layer level, as seen in the separation of PIN function during root development (Bilou et al., 2005). Duplication and subfunctionalization of the ancestral *PIN1* gene led to an uncoupling of auxin transport, resulting in distinct functions assigned to *SoPIN1a* and *PIN1* genes in the role of L1 auxin transport to create convergence points, subepidermal auxin flow, and the narrowing of auxin flux channels to refine emerging veins. Recent work in *Brachypodium distachyon* (Brachypodium) found that *Brachypodium SoPIN1* (BdSoPIN1) gene expression localizes predominately in the L1 layer while the two *Brachypodium* *PIN1* genes (*BdPIN1a* and *BdPIN1b*) are expressed subepidermally. Through this work the authors conclude that in *Brachypodium* *SoPIN1* functions in marking the sites of organ formation, while the *BdPIN1a* and *BdPIN1b* function in internalization of auxin flow to direct vascular development (O’Connor et al., 2014). Our work does not support such a distinct separation, but DR5: Venus localization differences found in e-2 (Fig. 6) suggest that while *SlSoPIN1a* functions predominately in L1 auxin transport, it also contributes to canalization processes as evidenced by the vascular phenotypes found in e-2 leaves (Fig. 4A-F).

While it appears that subfunctionalization of *PIN1* and *SoPIN1* genes play a role in auxin distribution at the tissue level (O’Connor et al., 2014), another important level for morphogenetic outcomes is that of developmental timing. As discerned from studies on the *slm-1* (*PIN10*/ Medtr7g106430) mutant, *Medicago truncatula SoPIN1* function is vital during juvenile leaf initiation; the juvenile leaf is completely abolished in *slm-1* and later leaf development has problems similar to those observed in e-2/slsopin1a (Zhou et al., 2011b). In *A. thaliana*, leaf development can be split into three developmental stages which are morphologically distinct (Guenot et al., 2012). In *atpin1*, the leaf phenotype clearly varies in the three leaf stages (Kwiatkowska, 2006), as leaf vasculature and shape gets progressively impaired with age, until there is a complete loss of lateral organ development after bolting (Guenot et al., 2012). There are two developmental stages in *S. lycopersicum* leaf formation; juvenile leaves and adult leaves (both before and after sympodial growth). In e-2/slsopin1a phyllotaxy abnormalities...
occur during juvenile development (Fig. 3A-E), and developmental problems prior to sympodial growth are observed, but the specification of organ type (flower vs leaf) remains identical to wild type. After e-2/issopin1a begin sympodial growth, specification of organ identity becomes extremely aberrant (Fig. 5A-L). Thus, auxin flux as regulated by IssOPIN1a is involved in organ identity throughout developmental age. Further, while SoPIN1 gene expression remains constant during the early stages of monopodial growth, expression levels change during sympodial meristem development both in time and at the tissue level to specify inflorescence identity (S6 Figure). Therefore, a uniting feature of all PIN1 and SoPIN1 loss of function mutants is the insight they provide into the role of auxin through developmental time.

3.6. Conclusion

PIN1 directed auxin transport during early shoot organogenesis regulates the iterative process of shoot development. The repeated developmental module of epidermal auxin transport and internal auxin transport is recycled during margin growth, leaf and leaflet formation, and positioning of vasculature. The importance of PIN1 in directing these processes is undisputed, yet it is still unknown how this mechanism has evolved through time. The extent of partitioning of auxin transport functions within PIN1 and SoPIN1 clades, and the functional consequences of this partitioning may provide explanations for the immense diversity in leaf form and inflorescence architecture seen in nature. The advent of available sequencing technologies for genome-scale gene identification and ability to undertake functional studies in a multitude of species has set the stage for comparative studies of developmental processes across Angiosperm clades. These studies should help uncover how the PIN1 and SoPIN1 clades contribute to the astounding morphological diversity found in the plant kingdom.

4. Materials and methods

4.1. Phylogenetic analysis

We used only sequences from species from fully sequenced genomes to ensure proper representation of the PIN gene family. All cDNA sequences were retrieved from either Pytozome (Goodstein et al., 2012), or through BLAST searches using genome databases available on the Sol Genomics Network (Fernandez-Pozo et al., 2015). Gene orthology was further confirmed through comparisons with previous phylogenetic work (Bennett et al., 2014; O’Connor et al., 2014). AtpPIN3 (AT1g70940) was used as the outgroup. All sequences were aligned using Multiple Sequence Comparison by Log- Expectation (MUSCLE) alignment (Edgar, 2004) on the EMBL-EBI bioinformatics web server (Li et al., 2015). Sequences were further trimmed using TrimAl (version 1.2rev59) with gap threshold set to 90% and a specified conservation minimum of 60% positions from the original alignment. Using the servers from the CIPRES Science Gateway (version 3.3; Miller et al., 2010). Maximum likelihood analysis was performed using RAxML-HPC2 (version 8.1.24; Stamatakis, 2014). Visualization and editing of trees was accomplished using FigTree (version 1.4.2; Rambaut and Drummond, 2009). Maximum Likelihood tree and alignment can be found at Treebase, http://purl.org/phylo/treebase/phylows/study/TB2: S18794, and in the manuscript Github repository, https://github.com/Iamciera/sister-of-pinn1-material.

4.2. Plant material and growth conditions

Seeds of e-2 (accession 3–705) and control (LA3130) were obtained from the Tomato Genetics Resource Center (TGRC). The transgenic DR5: Venus (cv M82) lines were previously described by and AtpPIN1: PIN1: GFP (cv Moneymaker) (Bayer et al., 2009). To ensure developmental synchronization, all seed lines were first sterilized with 50% bleach for 2 min, rinsed 10x with distilled water, and then placed on a moist paper towel in Phytotrays (Sigma-Aldrich) under dark conditions for two days before being placed in a growth chamber (temperature 22 °C, 16:8 light-dark cycle) for three days before transplanting to soil.

4.3. Microscopy

Microscopy of apices was performed using a Zeiss Discovery V12 stereomicroscope and photographed using an AxioCam MRc digital camera (Carl Zeiss Microlmaging, Thornwood, NY, USA). For fluorescent imaging, the microscope was equipped with an X-Cite 120 light source, a pentafluor GFP wideband cube (Zeiss KSC 295–831D, excitation H470/440 nm and dichroic mirror 495LP) and a long-pass emission filter (KS295–831WD, 500 nm). Images for immunolocalization and histology images were captured using a Nikon Eclipse E600 compound microscope and a Nikon digital camera (Nikon, Melville, New York, USA). Some photographs were adjusted for brightness and contrast and assembled into figures using Adobe Photoshop CS6 and Adobe Illustrator CS6 (Adobe Systems, San Jose, CA, USA).

4.4. Measurement of angle divergence and meristem size

Measurements of angles were made on plant apices of both wild type (LA3130) and e-2 were harvested 20 days after germination. All measurements were made on leaves before sympodial growth. The apices were then fixed in 3:1 acetic acid: ethanol and embedded in 100% paraffin. The apices were sectioned onto slides and stained with toluidine blue. Sections were visualized and photographed using microscopy methods as described above. In addition, older plants (50 days after germination) were also measured. In the older plant population, the leaflets were removed, leaving only the petiole, these were labeled and aerial photographed above the plant were taken using Olympus SP-500 UZ camera. ImageJ (version 1.46 R) was then used to calculate angle divergence of the first five to eight leaves. For quantifying meristem size, 12 individual plants were dissected to show how this mechanism has evolved through time. The extent of partitioning of auxin transport functions within PIN1 and SoPIN1 clades, and the functional consequences of this partitioning may provide explanations for the immense diversity in leaf form and inflorescence architecture seen in nature. The advent of available sequencing technologies for genome-scale gene identification and ability to undertake functional studies in a multitude of species has set the stage for comparative studies of developmental processes across Angiosperm clades. These studies should help uncover how the PIN1 and SoPIN1 clades contribute to the astounding morphological diversity found in the plant kingdom.

Plants were harvested 51 and 52 days after sowing, having six fully expanded leaves and were grown in a walk-in chamber (Conviron), temperature 22 °C, 16:8 light-dark cycle. Leaflets were removed from the petiole of L1–L7 and placed under non-reflective glass. Cameras (Olympus SP-500 UZ) were mounted using an Adorna; 36’ Deluxe Copy Stand, and remotely controlled with Cam2Com software (Sabsik). Normalization was made from measurements from rulers present in each photograph. Shape analysis was accomplished using ImageJ, by converting the photographs to binary images, with subsequent measurements of area, perimeter, circularity, aspect ratio, roundness, and solidity. Complexity was measured by counting all primary, secondary, and intercalary leaflets present on each leaf. Primary leaflets are the first leaves to develop off the rachis, secondary leaves form on the primary leaflets, and intercalary leaflets form between the primary leaves on the rachis. Total leaf complexity is the sum of all three leaflet
types. The binary images were then processed using the Momocs package in R (Bonhomme et al., 2014) to determine the elliptical Fourier descriptors. Analysis script is available at https://github.com/iamciera/sister-of-pin1-material.

4.6. Immunolocalization

Apices of 14 d old plants were fixed and vacuum infiltrated in 3:1 Methanol : acetic acid. Tissue was then taken through an ethanol series (10, 30, 50, 70, 85 2 x 100%) for thirty minutes each step mixed with PBS. Tissue was then incubated ethanolic: PEG15000 (Sigma-Aldrich) series (3:1, 1:1, 1:3, 2 x 1:1) at 45 °C. Tissue was embedded and mounted on saline Prep slides (Sigma-Aldrich) following tissue transfer methods previously described in Gao and Godkin, 1991 (Gao and Godkin, 1991). Blocking, secondary, and primary anti-body incubation was performed as previously described in (Bainbridge et al., 2008). Primary SlSoPIN1a antibodies were generated as described in (Bayer et al., 2009). SlSoPIN1a antibodies were diluted 1:200 and secondary antibody (Alexa Fluor 488-conjugated goat anti-rabbit) was diluted 1:300. Control slides, which were incubated with only secondary antibodies, were included in all experiments.

Author contributions

Conceived and designed the experiments: CM, NS, DK, DC. Performed the experiments: CM, DK, DC. Analyzed the data: CM, NS, DK, DC. Wrote the paper: CM, NS. Edited the paper: CM, NS, DK, DC.

Acknowledgments

The UC Davis Tomato Genetics Resource Center provided tomato germplasm, AtPIN1: PIN1: GFP and the DR5: VENUSx6 lines are gifts from Cris Kuhlemeier (University of Bern) and Naomi Ori (Hebrew University, Israel), respectively. We would like to thank Parshapti Upadhyay, Manmohanpal, Janancie Jones, Shiri Zimmerman, Gillette, Ish-Shalom, and Surbhi Chophla for technical assistance. Siobhan Brabaykuro generously provided the immunolocalization protocol. Thanks also to Siobhan Brady and Andrew Groover for their helpful comments.
